An introduction to proof mining

Paulo Oliva

In this talk we will look at some examples from mathematics where proofs carry more information than the theorem they prove. We will start with the simple proof that $\sqrt{2}$ is irrational, then look at Erdős proof that there are infinitely many prime numbers, and some proofs involving the PHP. Finally we will look at Cheney's proof of uniqueness for L_1 approximation. I will show how each proof actually has some extra information (e.g. algorithm or bound) enough to derive a stronger theorem. The difficulty in obtaining the extra information normally lies in the use of "non-computable" proof techniques such as compactness arguments or proof by contradiction. Proof mining aims to identify and extract extra information from (non-computable) proofs in order to derive stronger (new) theorems. Proof mining can also be viewed as a methodology for deriving results in "hard mathematics" from corresponding results in "soft mathematics", using Terence Tao's terminology. A brief introduction to the proof-theoretic techniques involved will be surveyed, time permitting.
